NONPARAMETRIC FILTERS

A popular alternative to Gaussian techniques are nonparametric filters. Nonparametric filters do not rely on a fixed functional form of the posterior, such as Gaussians. Instead, they approximate posteriors by a finite number of values, each roughly corresponding to a region in state space. Some nonparametric Bayes filters rely on a decomposition of the state space, in which each such value corresponds to the cumulative probability of the posterior density in a compact subregion of the state space. Others approximate the state space by random samples drawn from the posterior distribution. In all cases, the number of parameters used to approximate the posterior can be varied. The quality of the approximation depends on the number of parameters used to represent the posterior. As the number of parameters goes to infinity, nonparametric techniques tend to converge uniformly to the correct posterior (under specific smoothness assumptions).

This chapter discusses two nonparametric approaches for approximating posteriors over continuous spaces with finitely many values. The first decomposes the state space into finitely many regions, and represents the posterior by a histogram. A histogram assigns to each region a single cumulative probability; they are best thought of as piecewise constant approximations to a continuous density. The second technique represents posteriors by finitely many samples. The resulting filter is known as particle filter and has gained immense popularity in certain robotics problems.

Both types of techniques, histograms and particle filters, do not make strong parametric assumptions on the posterior density. In particular, they are well-suited to represent complex multimodal beliefs. For this reason, they are often the method of choice when a robot has to cope with phases of global uncertainty, and when it faces hard data association problems that yield separate, distinct hypotheses. However, the representational power of these techniques comes at the price of added computational com-

Table 4.1 The discrete Bayes fi Iter. Here x_i , x_k denote individual states.

plexity. Fortunately, both nonparametric techniques described in this chapter make it possible to adapt the number of parameters to the (suspected) complexity of the posterior. When the posterior is of low complexity (e.g., focused on a single state with a small margin of uncertainty), they use only small numbers of parameters. For complex posteriors, e.g., posteriors with many modes scattered across the state space, the number of parameters grows larger.

Techniques that can adapt the number of parameters to represent the posterior online are called *adaptive*. They are called *resource-adaptive* if they can adapt based on the computational resources available for belief computation. Resource-adaptive techniques play an important role in robotics. They enable robots to make decisions in real time, regardless of the computational resources available. Particle filters are often implemented as a resource-adaptive algorithm, by adapting the number of particles online based on the available computational resources.

4.1 THE HISTOGRAM FILTER

Histogram filters decompose the state space into finitely many regions, and represent the cumulative posterior for each region by a single probability value. When applied to discrete spaces, such filters are known as *discrete Bayes filters*. In continuous state spaces, they are known as *histogram filters*. We will first describe the discrete Bayes filter, and then discuss its use in continuous state spaces.

4.1.1 The Discrete Bayes Filter Algorithm

Discrete Bayes filters apply to problems with *finite* state spaces, that is, where the random variable X_t can take on finitely many values. We already encountered a discrete Bayes filter in Section 2.4.2, when discussing the example of a robot estimating the probability that a door is open. Some of the robotic mapping problems discussed in later chapters also involve discrete random variables. For example, occupancy grid mapping algorithms assume that each location in the environment is either occupied or free. The corresponding random variable is binary, that is, it can take on two different values. Thus, finite state spaces play an important role in robotics.

Table 4.1 provides pseudo-code for the discrete Bayes filter. This code is derived from the general Bayes filter in Table 2.1 by replacing the integration with a finite sum. The variables x_i and x_k denote individual states, of which there may only be finitely many. The belief at time t is an assignment of a probability to each state x_k , denoted $p_{k,t}$. Thus, the input to the algorithm is a discrete probability distribution $\{p_{k,t}\}$, along with the most recent control u_t and measurement z_t . Line 3 calculates the prediction, the belief for the new state based on the control alone. This prediction is then updated in Line 4, so as to incorporate the measurement. The discrete Bayes filter algorithm is popular in many areas of signal processing (such as speech recognition), where it is often referred to as the forward pass of a hidden Markov models.

4.1.2 Continuous State

Of particular interest in this book will be the use of discrete Bayes filters as an approximate inference tool for *continuous* state spaces. Such filters are called *histogram* filters. Histogram filters decompose a continuous state space into finitely many regions:

$$\operatorname{range}(X_t) = \mathbf{x}_{1,t} \cup \mathbf{x}_{2,t} \cup \dots \mathbf{x}_{K,t} \tag{4.1}$$

Here X_t is the familiar random variable describing the state of the robot at time t. The function $\operatorname{range}(X_t)$ denotes the state space, that is, the universe of possible values that X_t might assume. Each $\mathbf{x}_{k,t}$ describes a convex region. These regions together form a partitioning of the state space, that is, for each $i \neq k$ we have $\mathbf{x}_{i,t} \cap \mathbf{x}_{k,t} = \emptyset$ and $\bigcup_k \mathbf{x}_{k,t} = \operatorname{range}(X_t)$. A straightforward decomposition of a continuous state space is a multi-dimensional grid, where each $\mathbf{x}_{k,t}$ is a grid cell. Through the granularity of the decomposition, we can trade off accuracy and computational efficiency. Fine-

grained decompositions infer smaller approximation errors than coarse ones, but at the expense of increased computational complexity.

As we already discussed, the discrete Bayes filter assigns to each region $\mathbf{x}_{k,t}$ a probability, $p_{k,t}$. Within each region, the discrete Bayes filter carries no further information on the belief distribution. Thus, the posterior becomes a piecewise constant PDF, which assigns a uniform probability to each state x_t within each region $\mathbf{x}_{k,t}$:

$$p(x_t) = \frac{p_{k,t}}{|\mathbf{x}_{k,t}|} \tag{4.2}$$

Here $|\mathbf{x}_{k,t}|$ is the volume of the region $\mathbf{x}_{k,t}$.

If the state space is truly discrete, the conditional probabilities $p(\mathbf{x}_{k,t} \mid u_t, \mathbf{x}_{i,t-1})$ and $p(z_t \mid \mathbf{x}_{k,t})$ are well-defined, and the algorithm can be implemented as stated. In continuous state spaces, one is usually given the densities $p(x_t \mid u_t, x_{t-1})$ and $p(z_t \mid x_t)$, which are defined for individual states (and not for regions in state space). For cases where each region $\mathbf{x}_{k,t}$ is small and of the same size, these densities are usually approximated by substituting $\mathbf{x}_{k,t}$ by a representative of this region. For example, we might simply "probe" using the mean state in $\mathbf{x}_{k,t}$

$$\hat{x}_{k,t} = |\mathbf{x}_{k,t}|^{-1} \int_{\mathbf{x}_{k,t}} x_t \, dx_t \tag{4.3}$$

One then simply replaces

$$p(z_t \mid \mathbf{x}_{k,t}) \approx p(z_t \mid \hat{x}_{k,t}) \tag{4.4}$$

$$p(\mathbf{x}_{k,t} \mid u_t, \mathbf{x}_{i,t-1}) \approx \frac{\eta}{|\mathbf{x}_{k,t}|} p(\hat{x}_{k,t} \mid u_t, \hat{x}_{i,t-1})$$

$$(4.5)$$

These approximations are the result of the piecewise uniform interpretation of the discrete Bayes filter stated in (4.2), and a linearization similar to the one used by EKFs.

To see that (4.4) is a reasonable approximation, we note that $p(z_t \mid \mathbf{x}_{k,t})$ can be expressed as the following integral:

$$p(z_t \mid \mathbf{x}_{k,t}) = \frac{p(z_t, \mathbf{x}_{k,t})}{p(\mathbf{x}_{k,t})}$$

$$= \frac{\int_{\mathbf{x}_{k,t}} p(z_t, x_t) dx_t}{\int_{\mathbf{x}_{k,t}} p(x_t) dx_t}$$

$$= \frac{\int_{\mathbf{x}_{k,t}} p(z_t \mid x_t) p(x_t) dx_t}{\int_{\mathbf{x}_{k,t}} p(x_t) dx_t}$$

$$\stackrel{(4.2)}{=} \frac{\int_{\mathbf{x}_{k,t}} p(z_t \mid x_t) \frac{p_{k,t}}{\mid \mathbf{x}_{k,t}\mid} dx_t}{\int_{\mathbf{x}_{k,t}} \frac{p_{k,t}}{\mid \mathbf{x}_{k,t}\mid} dx_t}$$

$$= \frac{\int_{\mathbf{x}_{k,t}} p(z_t \mid x_t) dx_t}{\int_{\mathbf{x}_{k,t}} 1 dx_t}$$

$$= |\mathbf{x}_{k,t}|^{-1} \int_{\mathbf{x}_{k,t}} p(z_t \mid x_t) dx_t$$

$$(4.6)$$

This expression is an exact description of the desired probability under the piecewise uniform distribution model in (4.2). If we now approximate $p(z_t \mid x_t)$ by $p(z_t \mid \hat{x}_{k,t})$ for $x_t \in \mathbf{x}_{k,t}$, we obtain

$$p(z_{t} | \mathbf{x}_{k,t}) \approx |\mathbf{x}_{k,t}|^{-1} \int_{\mathbf{x}_{k,t}} p(z_{t} | \hat{x}_{k,t}) dx_{t}$$

$$= |\mathbf{x}_{k,t}|^{-1} p(z_{t} | \hat{x}_{k,t}) \int_{\mathbf{x}_{k,t}} 1 dx_{t}$$

$$= |\mathbf{x}_{k,t}|^{-1} p(z_{t} | \hat{x}_{k,t}) |\mathbf{x}_{k,t}|$$

$$= p(z_{t} | \hat{x}_{k,t})$$
(4.7)

which is the approximation stated above in (4.4).

The derivation of the approximation to $p(\mathbf{x}_{k,t} \mid u_t, \mathbf{x}_{i,t-1})$ in (4.5) is slightly more involved, since regions occur on both sides of the conditioning bar. In analogy to our transformation above, we obtain:

$$p(\mathbf{x}_{k,t} \mid u_t, \mathbf{x}_{i,t-1}) = \frac{p(\mathbf{x}_{k,t}, \mathbf{x}_{i,t-1} \mid u_t)}{p(\mathbf{x}_{i,t-1} \mid u_t)} = \frac{\int_{\mathbf{x}_{k,t}} \int_{\mathbf{x}_{i,t-1}} p(x_t, x_{t-1} \mid u_t) dx_t, dx_{t-1}}{\int_{\mathbf{x}_{i,t-1}} p(x_{t-1} \mid u_t) dx_{t-1}}$$

$$= \frac{\int_{\mathbf{x}_{k,t}} \int_{\mathbf{x}_{i,t-1}} p(x_t \mid u_t, x_{t-1}) p(x_{t-1} \mid u_t) dx_t, dx_{t-1}}{\int_{\mathbf{x}_{i,t-1}} p(x_{t-1} \mid u_t) dx_{t-1}}$$
(4.8)

We now exploit the Markov assumption, which implies independence between x_{t-1} and u_t , and thus $p(x_{t-1} \mid u_t) = p(x_{t-1})$:

$$p(\mathbf{x}_{k,t} \mid u_{t}, \mathbf{x}_{i,t-1}) = \frac{\int_{\mathbf{x}_{k,t}} \int_{\mathbf{x}_{i,t-1}} p(x_{t} \mid u_{t}, x_{t-1}) p(x_{t-1}) dx_{t}, dx_{t-1}}{\int_{\mathbf{x}_{i,t-1}} p(x_{t-1}) dx_{t-1}}$$

$$= \frac{\int_{\mathbf{x}_{k,t}} \int_{\mathbf{x}_{i,t-1}} p(x_{t} \mid u_{t}, x_{t-1}) \frac{p_{i,t-1}}{|\mathbf{x}_{i,t-1}|} dx_{t}, dx_{t-1}}{\int_{\mathbf{x}_{i,t-1}} \frac{p_{i,t-1}}{|\mathbf{x}_{i,t-1}|} dx_{t-1}}$$

$$= \frac{\int_{\mathbf{x}_{k,t}} \int_{\mathbf{x}_{i,t-1}} p(x_{t} \mid u_{t}, x_{t-1}) dx_{t}, dx_{t-1}}{\int_{\mathbf{x}_{i,t-1}} 1 dx_{t-1}}$$

$$= |\mathbf{x}_{i,t-1}|^{-1} \int_{\mathbf{x}_{k,t}} \int_{\mathbf{x}_{i,t-1}} p(x_{t} \mid u_{t}, x_{t-1}) dx_{t}, dx_{t-1}$$

$$(4.9)$$

If we now approximate $p(x_t \mid u_t, x_{t-1})$ by $p(\hat{x}_{k,t} \mid u_t, \hat{x}_{i,t-1})$ as before, we obtain the following approximation. Note that the normalizer η becomes necessary to ensure that the approximation is a valid probability distribution:

$$p(\mathbf{x}_{k,t} \mid u_t, \mathbf{x}_{i,t-1})$$

$$\approx \eta |\mathbf{x}_{i,t-1}|^{-1} \int_{\mathbf{x}_{k,t}} \int_{\mathbf{x}_{i,t-1}} p(\hat{x}_{k,t} \mid u_t, \hat{x}_{i,t-1}) dx_t, dx_{t-1}$$

$$= \eta |\mathbf{x}_{i,t-1}|^{-1} p(\hat{x}_{k,t} \mid u_t, \hat{x}_{i,t-1}) \int_{\mathbf{x}_{k,t}} \int_{\mathbf{x}_{i,t-1}} 1 dx_t, dx_{t-1}$$

$$= \eta |\mathbf{x}_{i,t-1}|^{-1} p(\hat{x}_{k,t} \mid u_t, \hat{x}_{i,t-1}) |\mathbf{x}_{k,t}| |\mathbf{x}_{i,t-1}|$$

$$= \eta |\mathbf{x}_{k,t}| p(\hat{x}_{k,t} \mid u_t, \hat{x}_{i,t-1})$$
(4.10)

If all regions are of equal size (meaning that $|\mathbf{x}_{k,t}|$ is the same for all k), we can simply omit the factor $|\mathbf{x}_{k,t}|$, since it is subsumed by the normalizer. The resulting discrete Bayes filter is then equivalent to the algorithm outlined in Table 4.1. If implemented as stated there, the auxiliary parameters \bar{p}_k do not constitute a probability distribution, since they are not normalized (compare Line 3 to (4.10)). However, normalization takes place in Line 4, so that the output parameters are indeed a valid probability distribution.

4.1.3 Decomposition Techniques

In robotics, decomposition techniques of continuous state spaces come into two basic flavors: *static* and *dynamic*. Static techniques rely on a fixed decomposition that is chosen in advance, irrespective of the shape of the posterior that is being approximated. Dynamic techniques adapt the decomposition to the specific shape of the posterior distribution. Static techniques are usually easier to implement, but they can be wasteful with regards to computational resources.

A primary example of a dynamic decomposition technique is the family of *density trees*. Density trees decompose the state space recursively, in ways that adapt the resolution to the posterior probability mass. The intuition behind this decomposition is that the level of detail in the decomposition is a function of the posterior probability: The less likely a region, the coarser the decomposition. Figure 4.1 illustrates the difference between a static grid representation and a density tree representation for a two-dimensional probability density. While both representations have the same approximation quality, the density tree is more compact than the grid representation. Dynamic techniques like density trees can often cut the computation complexity by orders of magnitude over static ones, yet they require additional implementation effort.

An effect similar to that of dynamic decompositions can be achieved by *selective updating*. When updating a posterior represented by a grid, selective techniques update a fraction of all grid cells only. A common implementation of this idea updates only those grid cells whose posterior probability exceeds a user-specified threshold. Selective updating can be viewed as a hybrid decomposition, which decomposes the state space into a fine grained grid and one large set that contains all regions not chosen by the selective update procedure. In this light, it can be thought of as a dynamic decomposition technique, since the decision as to which grid cells to consider during the update is made online, based on the shape of the posterior distribution. Selective updating techniques can reduce the computational effort involved in updating beliefs by many orders of magnitude. They make it possible to use grid decompositions in spaces of three or more dimensions.

The mobile robotics literature often distinguishes topological from metric representations of space. While no clear definition of these terms exist, topological representations are often thought of as course graph-like representations, where nodes in the graph correspond to significant places (or features) in the environment. For indoor environments, such places may correspond to intersections, T-junctions, dead ends, and so on. The resolution of such decompositions, thus, depends on the structure of the environment. Alternatively, one might decompose the state space using regularly-

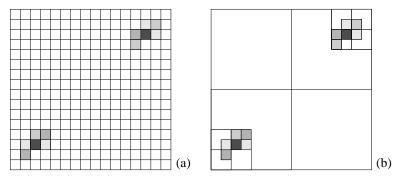

Figure 4.1 (a) Grid based representation of a two-dimensional probability density. The probability density concentrates on the upper right and lower left part of the state space. (b) Density tree representation of the same distribution.

spaced grids. Such a decomposition does not depend on the shape and location of the environmental features. Grid representations are often thought of as metric although, strictly speaking, it is the embedding space that is metric, not the decomposition. In mobile robotics, the spatial resolution of grid representations tends to be higher than that of topological representations. For instance, some of the examples in Chapter 7 use grid decompositions with cell sizes of 10 centimeters or less. This increased accuracy comes at the expense of increased computational costs.

4.1.4 Binary Bayes Filters With Static State

Certain problems in robotics are best formulated as estimation problems with binary state that does not change over time. Problems of this type arise if a robot estimates a fixed binary quantity in the environment from a sequence of sensor measurements. Since the state is static, the belief is a function of the measurements:

$$bel_t(x) = p(x \mid z_{1:t}, u_{1:t}) = p(x \mid z_{1:t})$$
 (4.11)

where the state is chosen from two possible values, denoted by x and $\neg x$. In particular, we have $bel_t(\neg x) = 1 - bel_t(x)$. The lack of a time index for the state x reflects the fact that the state does not change.

Naturally, binary estimation problems of this type can be tackled using the discrete Bayes filter in Table 4.1. However, the belief is commonly implemented as a $log\ odds$ ratio. The odds of a state x is defined as the ratio of the probability of this event

```
1: Algorithm binary_Bayes_filter(l_{t-1}, z_t):
2: l_t = l_{t-1} + \log \frac{p(x|z_t)}{1 - p(x|z_t)} - \log \frac{p(x)}{1 - p(x)}
3: return l_t
```

Table 4.2 The binary Bayes filter in log odds form with an inverse measurement model. Here l_t is the log odds of the posterior belief over a binary state variable that does not change over time.

divided by the probability of its negate

$$\frac{p(x)}{p(\neg x)} = \frac{p(x)}{1 - p(x)} \tag{4.12}$$

The log odds is the logarithm of this expression

$$l(x) := \log \frac{p(x)}{1 - p(x)}$$
 (4.13)

Log odds assume values from $-\infty$ to ∞ . The Bayes filter for updating beliefs in log odds representation is computationally elegant. It avoids truncation problems that arise for probabilities close to 0 or 1.

Table 4.2 provides the basic update algorithm. This algorithm is additive; in fact, any algorithm that increment and decrement a variable in response to measurements can be interpreted as a Bayes filter in log odds form. This binary Bayes filter uses an *inverse measurement model* $p(x \mid z_t)$, instead of the familiar forward model $p(z_t \mid x)$. The inverse measurement model specifies a distribution over the (binary) state variable as a function of the measurement z_t . Inverse models are often used in situations where measurements are more complex than the binary state. An example of such a situation is the problem of estimating whether or not a door is closed, from camera images. Here the state is extremely simple, but the space of all measurements is huge. It is easier to devise a function that calculates a probability of a door being closed from a camera image, than describing the distribution over all camera images that show a closed door. In other words, it is easier to implement an inverse than a forward sensor model.

As the reader easily verifies from our definition of the log odds (4.13), the belief $bel_t(x)$ can be recovered from the log odds ratio l_t by the following equation:

$$bel_t(x) = 1 - \frac{1}{1 + \exp\{l_t\}}$$
 (4.14)

To verify the correctness of our binary Bayes filter algorithm, we briefly restate the basic filter equation with the Bayes normalizer made explicit:

$$p(x \mid z_{1:t}) = \frac{p(z_t \mid x, z_{1:t-1}) \ p(x \mid z_{1:t-1})}{p(z_t \mid z_{1:t-1})}$$

$$= \frac{p(z_t \mid x) \ p(x \mid z_{1:t-1})}{p(z_t \mid z_{1:t-1})}$$
(4.15)

We now apply Bayes rule to the measurement model $p(z_t \mid x)$:

$$p(z_t \mid x) = \frac{p(x \mid z_t) \ p(z_t)}{p(x)} \tag{4.16}$$

and obtain

$$p(x \mid z_{1:t}) = \frac{p(x \mid z_t) \ p(z_t) \ p(x \mid z_{1:t-1})}{p(x) \ p(z_t \mid z_{1:t-1})}. \tag{4.17}$$

By analogy, we have for the opposite event $\neg x$:

$$p(\neg x \mid z_{1:t}) = \frac{p(\neg x \mid z_t) \ p(z_t) \ p(\neg x \mid z_{1:t-1})}{p(\neg x) \ p(z_t \mid z_{1:t-1})}$$
(4.18)

Dividing (4.17) by (4.18) leads to cancellation of various difficult-to-calculate probabilities:

$$\frac{p(x \mid z_{1:t})}{p(\neg x \mid z_{1:t})} = \frac{p(x \mid z_t)}{p(\neg x \mid z_t)} \frac{p(x \mid z_{1:t-1})}{p(\neg x \mid z_{1:t-1})} \frac{p(\neg x)}{p(x)}$$

$$= \frac{p(x \mid z_t)}{1 - p(x \mid z_t)} \frac{p(x \mid z_{1:t-1})}{1 - p(x \mid z_{1:t-1})} \frac{1 - p(x)}{p(x)}$$
(4.19)

We denote the log odds ratio of the belief $bel_t(x)$ by $l_t(x)$. The log odds belief at time t is given by the logarithm of (4.19).

$$l_{t}(x) = \log \frac{p(x \mid z_{t})}{1 - p(x \mid z_{t})} + \log \frac{p(x \mid z_{1:t-1})}{1 - p(x \mid z_{1:t-1})} + \log \frac{1 - p(x)}{p(x)}$$

$$= \log \frac{p(x \mid z_{t})}{1 - p(x \mid z_{t})} - \log \frac{p(x)}{1 - p(x)} + l_{t-1}(x)$$
(4.20)

Here p(x) is the *prior* probability of the state x. As (4.20), each measurement update involves the addition of the prior (in log odds form). The prior also defines the log odds of the initial belief before processing any sensor measurement:

$$l_0(x) = \log \frac{1 - p(x)}{p(x)} \tag{4.21}$$

4.2 THE PARTICLE FILTER

4.2.1 Basic Algorithm

The particle filter is an alternative nonparametric implementation of the Bayes filter. Just like histogram filters, particle filters approximate the posterior by a finite number of parameters. However, they differ in the way these parameters are generated, and in which they populate the state space. The key idea of the particle filter is to represent the posterior $bel(x_t)$ by a set of random state samples drawn from this posterior. Figure ?? illustrates this idea for a Gaussian. Instead of representing the distribution by a parametric form (the exponential function that defines the density of a normal distribution), particle filters represent a distribution by a set of samples drawn from this distribution. Such a representation is approximate, but it is nonparametric, and therefore can represent a much broader space of distributions than, for example, Gaussians.

In particle filters, the samples of a posterior distribution are called *particles* and are denoted

$$\mathcal{X}_t := x_t^{[1]}, x_t^{[2]}, \dots, x_t^{[M]} \tag{4.22}$$

Each particle $x_t^{[m]}$ (with $1 \le m \le M$) is a concrete instantiation of the state at time t, that is, a hypothesis as to what the true world state may be at time t. Here M denotes

```

```

Table 4.3 The particle filter algorithm, a variant of the Bayes filter based on importance sampling.

the number of particles in the particle set \mathcal{X}_t . In practice, the number of particles M is often a large number, e.g., M=1,000. In some implementations M is a function of t or of other quantities related to the belief $bel(x_t)$.

The intuition behind particle filters is to approximate the belief $bel(x_t)$ by the set of particles \mathcal{X}_t . Ideally, the likelihood for a state hypothesis x_t to be included in the particle set \mathcal{X}_t shall be proportional to its Bayes filter posterior $bel(x_t)$:

$$x_t^{[m]} \sim p(x_t \mid z_{1:t}, u_{1:t})$$
 (4.23)

As a consequence of (4.23), the denser a subregion of the state space is populated by samples, the more likely it is that the true state falls into this region. As we will discuss below, the property (4.23) holds only asymptotically for $M\uparrow\infty$ for the standard particle filter algorithm. For finite M, particles are drawn from a slightly different distribution. In practice, this difference is negligible as long as the number of particles is not too small (e.g., $M\geq 100$).

Just like all other Bayes filter algorithms discussed thus far, the particle filter algorithm constructs the belief $bel(x_t)$ recursively from the belief $bel(x_{t-1})$ one time step earlier. Since beliefs are represented by sets of particles, this means that particle filters

construct the particle set \mathcal{X}_t recursively from the set \mathcal{X}_{t-1} . The most basic variant of the particle filter algorithm is stated in Table 4.3. The input of this algorithm is the particle set \mathcal{X}_{t-1} , along with the most recent control u_t and the most recent measurement z_t . The algorithm then first constructs a temporary particle set $\bar{\mathcal{X}}$ which is reminiscent (but not equivalent) to the belief $\overline{bel}(x_t)$. It does this by systematically processing each particle $x_{t-1}^{[m]}$ in the input particle set \mathcal{X}_{t-1} as follows.

- 1. Line 4 generates a hypothetical state $x_t^{[m]}$ for time t based on the particle $x_{t-1}^{[m]}$ and the control u_t . The resulting sample is indexed by m, indicating that it is generated from the m-th particle in \mathcal{X}_{t-1} . This step involves sampling from the next state distribution $p(x_t \mid u_t, x_{t-1})$. To implement this step, one needs to be able to sample from $p(x_t \mid u_t, x_{t-1})$. The ability to sample from the state transition probability is not given for arbitrary distributions $p(x_t \mid u_t, x_{t-1})$. However, many major distributions in this book possess efficient algorithms for generating samples. The set of particles resulting from iterating Step 4 M times is the filter's representation of $\overline{bel}(x_t)$.
- 2. Line 5 calculates for each particle $x_t^{[m]}$ the so-called *importance factor*, denoted $w_t^{[m]}$. Importance factors are used to incorporate the measurement z_t into the particle set. The importance, thus, is the probability of the measurement z_t under the particle $x_t^{[m]}$, that is, $w_t^{[m]} = p(z_t \mid x_t^{[m]})$. If we interpret $w_t^{[m]}$ as the *weight* of a particle, the set of weighted particles represents (in approximation) the Bayes filter posterior $bel(x_t)$.
- 3. The real "trick" of the particle filter algorithm occurs in Lines 8 through 11 in Table 4.3. These lines implemented what is known as resampling or importance resampling. The algorithm draws with replacement M particles from the temporary set $\bar{\mathcal{X}}_t$. The probability of drawing each particle is given by its importance weight. Resampling transforms a particle set of M particles into another particle set of the same size. By incorporating the importance weights into the resampling process, the distribution of the particles change: whereas before the resampling step, they were distribution according to $\overline{bel}(x_t)$, after the resampling they are distributed (approximately) according to the posterior $bel(x_t) = \eta \ p(z_t \mid x_t^{[m]}) \overline{bel}(x_t)$. In fact, the resulting sample set usually possesses many duplicates, since particles are drawn with replacement. More important are the particles that are not contained in \mathcal{X}_t : those tend to be the particles with lower importance weights.

The resampling step has the important function to force particles back to the posterior $bel(x_t)$. In fact, an alternative (and usually inferior) version of the particle filter would never resample, but instead would maintain for each particle an importance weight

that is initialized by 1 and updated multiplicatively:

$$w_t^{[m]} = p(z_t \mid x_t^{[m]}) w_{t-1}^{[m]}$$
(4.24)

Such a particle filter algorithm would still approximate the posterior, but many of its particles would end up in regions of low posterior probability. As a result, it would require many more particles; how many depends on the shape of the posterior. The resampling step is a probabilistic implementation of the Darwinian idea of *survival* of the fittest: It refocuses the particle set to regions in state space with high posterior probability. By doing so, it focuses the computational resources of the filter algorithm to regions in the state space where they matter the most.

4.2.2 Importance Sampling

For the derivation of the particle filter, it shall prove useful to discuss the resampling step in more detail. Figure 4.2 illustrates the intuition behind the resampling step. Figure 4.2a shows a density function f of a probability distribution called the *target distribution*. What we would like to achieve is to obtain a sample from f. However, sampling from f directly may not be possible. Instead, we can generate particles from a related density, labeled g in Figure 4.2b. The distribution that corresponds to the density g is called *proposal distribution*. The density g must be such that f(x) > 0 implies g(x) > 0, so that there is a non-zero probability to generate a particle when sampling from g for any state that might be generated by sampling from f. However, the resulting particle set, shown at the bottom of Figure 4.2b, is distributed according to g, not to f. In particular, for any interval f0 f1 f1 range(f2) (or more generally, any Borel set f3) the empirical count of particles that fall into f3 converges to the integral of f3 under f4:

$$\frac{1}{M} \sum_{m=1}^{M} I(x^{[m]} \in A) \longrightarrow \int_{A} g(x) dx \tag{4.25}$$

To offset this difference between f and g, particles $x^{[m]}$ are weighted by the quotient

$$w^{[m]} = \frac{f(x^{[m]})}{g(x^{[m]})} \tag{4.26}$$

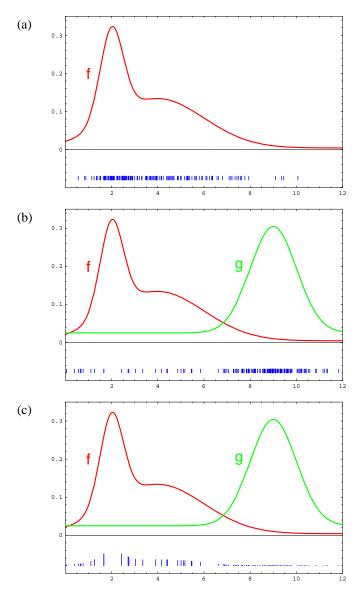

Figure 4.2 Illustration of importance factors in particle fi Iters: (a) We seek to approximate the target density f. (b) Instead of sampling from f directly, we can only generate samples from a different density, g. Samples drawn from g are shown at the bottom of this diagram. (c) A sample of f is obtained by attaching the weight f(x)/g(x) to each sample x. In particle fi Iters, f corresponds to the belief $bel(x_t)$ and g to the belief $\overline{bel}(x_t)$.

This is illustrated by Figure 4.2c: The vertical bars in this figure indicate the magnitude of the importance weights. Importance weights are the non-normalized probability mass of each particle. In particular, we have

$$\left[\sum_{m=1}^{M} w^{[m]}\right]^{-1} \sum_{m=1}^{M} I(x^{[m]} \in A) \ w^{[m]} \longrightarrow \int_{A} f(x) \ dx \tag{4.27}$$

where the first term serves as the normalizer for all importance weights. In other words, even though we generated the particles from the density g, the appropriately weighted particles converge to the density f.

The specific convergence involves an integration over a set A. Clearly, a particle set represents a discrete distribution, whereas f is continuous in our example. Because of this, there is no density that could be associated with a set of particles. The convergence, thus, is over the cumulative distribution function of f, not the density itself (hence the integration over A). A nice property of importance sampling is that it converges to the true density if g(x)>0 whenever f(x)>0. In most cases, the rate of convergence is in $O(\frac{1}{\sqrt{M}})$, where M is the number of samples. The constant factor depends on the similarity of f(s) and g(s).

In particle filters, the density f corresponds to the target belief $bel(x_t)$. Under the (asymptotically correct) assumption that the particles in \mathcal{X}_{t-1} are distributed according to $bel(x_{t-1})$, the density g corresponds to the product distribution:

$$p(x_t \mid u_t, x_{t-1}) \ bel(x_{t-1}) \tag{4.28}$$

This distribution is called the *proposal distribution*.

4.2.3 Mathematical Derivation of the PF

To derive particle filters mathematically, it shall prove useful to think of particles as samples of state sequences

$$x_{0:t}^{[m]} = x_0^{[m]}, x_1^{[m]}, \dots, x_t^{[m]}$$
 (4.29)

It is easy to modify the algorithm accordingly: Simply append to the particle $x_t^{[m]}$ the sequence of state samples from which it was generated $x_{0:t-1}^{[m]}$. This particle filter

calculates the posterior over all state sequences:

$$bel(x_{0:t}) = p(x_{0:t} \mid u_{1:t}, z_{1:t})$$
(4.30)

instead of the belief $bel(x_t) = p(x_t \mid u_{1:t}, z_{1:t})$. Admittedly, the space over all state sequences is huge, and covering it with particles is usually plainly infeasible. However, this shall not deter us here, as this definition serves only as the means to derive the particle filter algorithm in Table 4.2.

The posterior $bel(x_{0:t})$ is obtained analogously to the derivation of $bel(x_t)$ in Section 2.4.3. In particular, we have

$$p(x_{0:t} \mid z_{1:t}, u_{1:t})$$

$$\stackrel{\text{Bayes}}{=} \eta p(z_t \mid x_{0:t}, z_{1:t-1}, u_{1:t}) p(x_{0:t} \mid z_{1:t-1}, u_{1:t})$$

$$\stackrel{\text{Markov}}{=} \eta p(z_t \mid x_t) p(x_{0:t} \mid z_{1:t-1}, u_{1:t})$$

$$= \eta p(z_t \mid x_t) p(x_t \mid x_{0:t-1}, z_{1:t-1}, u_{1:t}) p(x_{0:t-1} \mid z_{1:t-1}, u_{1:t})$$

$$\stackrel{\text{Markov}}{=} \eta p(z_t \mid x_t) p(x_t \mid x_{t-1}, u_t) p(x_{0:t-1} \mid z_{1:t-1}, u_{1:t-1})$$

$$\stackrel{\text{Markov}}{=} \eta p(z_t \mid x_t) p(x_t \mid x_{t-1}, u_t) p(x_{0:t-1} \mid z_{1:t-1}, u_{1:t-1})$$

$$\stackrel{\text{Markov}}{=} (4.31)$$

Notice the absence of integral signs in this derivation, which is the result of maintaining all states in the posterior, not just the most recent one as in Section 2.4.3.

The derivation is now carried out by induction. The initial condition is trivial to verify, assuming that our first particle set is obtained by sampling the prior $p(x_0)$. Let us assume that the particle set at time t-1 is distributed according to $bel(x_{0:t-1})$. For the m-th particle $x_{0:t-1}^{[m]}$ in this set, the sample $x_t^{[m]}$ generated in Step 4 of our algorithm is generated from the proposal distribution:

$$p(x_t \mid x_{t-1}, u_t) \ bel(x_{0:t-1})$$

$$= p(x_t \mid x_{t-1}, u_t) \ p(x_{0:t-1} \mid z_{0:t-1}, u_{0:t-1})$$
(4.32)

With

S4 Chapter 4

The constant η plays no role since the resampling takes place with probabilities *proportional* to the importance weights. By resampling particles with probability proportional to $w_t^{[m]}$, the resulting particles are indeed distributed according to the product of the proposal and the importance weights $w_t^{[m]}$:

$$\eta w_t^{[m]} p(x_t \mid x_{t-1}, u_t) p(x_{0:t-1} \mid z_{0:t-1}, u_{0:t-1}) = bel(x_{0:t})$$
(4.34)

(Notice that the constant factor η here differs from the one in (4.33).) The algorithm in Table 4.2 follows now from the simple observation that if $x_{0:t}^{[m]}$ is distributed according to $bel(x_{0:t})$, then the state sample $x_t^{[m]}$ is (trivially) distributed according to $bel(x_t)$.

As we will argue below, this derivation is only correct for $M \longrightarrow \infty$, due to a laxness in our consideration of the normalization constants. However, even for finite M it explains the intuition behind the particle filter.

4.2.4 Properties of the Particle Filter

Particle filters are approximate and as such subject to approximation errors. There are four complimentary sources of approximation error, each of which gives rise to improved versions of the particle filter.

1. The first approximation error relates to the fact that only finitely many particles are used. This artifact introduces a systematic bias in the posterior estimate. To see, consider the extreme case of M=1 particle. In this case, the loop in Lines 3 through 7 in Table 4.3 will only be executed once, and $\bar{\mathcal{X}}_t$ will contain only a single particle, sampled from the motion model. The key insight is that the resampling step (Lines 8 through 11 in Table 4.3) will now deterministically accept this sample, regardless of its importance factor $w_t^{[m]}$. Put differently, the measurement probability $p(z_t \mid x_t^{[m]})$ plays no role in the result of the update, and neither does z_t . Thus, if M=1, the particle filter generates particles from the probability

$$p(x_t \mid u_{1:t}) \tag{4.35}$$

instead of the desired posterior $p(x_t \mid u_{1:t}, z_{1:t})$. It flatly ignores all measurements. How can this happen?

The culprit is the normalization, implicit in the resampling step. When sampling in proportion to the importance weights (Line 9 of the algorithm), $\boldsymbol{w}_t^{[m]}$ becomes

its own normalizer if M=1:

$$p(\text{draw } x_t^{[m]} \text{ in Line 9}) = \frac{w_t^{[m]}}{w_t^{[m]}} = 1$$
 (4.36)

In general, the problem is that the non-normalized values $w_t[m]$ are drawn from an M-dimensional space, but after normalization they reside in a space of dimension M-1. This is because after normalization, the m-th weight can be recovered from the M-1 other weights by subtracting those from 1. Fortunately, for larger values of M, the effect of loss of dimensionality, or degrees of freedom, becomes less and less pronounced.

2. A second source of error in the particle filter relates to the randomness introduced in the resampling phase. To understand this error, it will once again be useful to consider the extreme case, which is that of a robot whose state does not change. Sometimes, we know for a fact that $x_t = x_{t-1}$. A good example is that of mobile robot localization, for a non-moving robot. Let us furthermore assume that the robot possesses no sensors, hence it cannot estimate the state, and that it is unaware of the state. Initially, our particle set \mathcal{X}_0 will be generated from the prior; hence particles will be spread throughout the state space. The random nature of the resampling step (Line 8 in the algorithm) will regularly fail to draw a state sample $x^{[m]}$. However, since our state transition is deterministic, no new states will be introduced in the forward sampling step (Line 4). The result is quite daunting: With probability one, M identical copies of a single state will survive; the diversity will disappear due to the repetitive resampling. To an outside observer, it may appear that the robot has uniquely determined the world state—an apparent contradiction to the fact that the robot possesses no sensors.

This example hints at an important limitation of particle filters with immense practical ramifications. In particular, the resampling process induces a loss of diversity in the particle population, which in fact manifests itself as approximation error. Such error is called *variance* of the estimator: Even though the variance of the particle set itself decreases, the variance of the particle set as an estimator of the true belief increases. Controlling this variance, or error, of the particle filter is essential for any practical implementation.

There exist two major strategies for variance reduction. First, one may reduce the frequency at which resampling takes place. When the state is known to be static $(x_t = x_{t-1})$ one should never resample. This is the case, for example, in mobile robot localization: When the robot stops, resampling should be suspended (and in fact it is usually a good idea to suspend the integration of measurements as well). Even if the state changes, it is often a good idea to reduce the frequency of resampling. Multiple measurements can always be integrated via multiplicatively

                  return \bar{\mathcal{X}}_t
```

Table 4.4 Low variance resampling for the particle filter. This routine uses a single random number to sample from the particle set $\mathcal X$ with associated weights $\mathcal W$, yet the probability of a particle to be resampled is still proportional to its weight. Furthermore, the sampler is efficient: Sampling M particles requires O(M) time.

updating the importance factor as noted above. More specifically, it maintains the importance weight in memory and updates them as follows:

$$w_t^{[m]} = \begin{cases} 1 & \text{if resampling took place} \\ p(z_t \mid x_t^{[m]}) \ w_{t-1}^{[m]} & \text{if no resampling took place} \end{cases}$$
(4.37)

The choice of when to resample is intricate and requires practical experience: Resampling too often increases the risk of losing diversity. If one samples too infrequently, many samples might be wasted in regions of low probability. A standard approach to determining whether or not resampling should be performed is to measure the variance of the importance weights. The variance of the weights relates to the efficiency of the sample based representation. If all weights are identical, then the variance is zero and no resampling should be performed. If, on the other hand, the weights are concentrated on a small number of samples, then the weight variance is high and resampling should be performed.

The second strategy for reducing the sampling error is known as *low variance* sampling. Table 4.4 depicts an implementation of a low variance sampler. The basic idea is that instead of selecting samples independently of each other in the

Figure 4.3 Principle of the low variance resampling procedure. We choose a random number r and then select those particles that correspond to $u = r + (m-1) \cdot M^{-1}$ where $m = 1, \dots, M$.

resampling process (as is the case for the basic particle filter in Table 4.3), the selection involves a sequential stochastic process.

Instead of choosing M random numbers and selecting those particles that correspond to these random numbers, this algorithm computes a single random number and selects samples according to this number but still with a probability proportional to the sample weight. This is achieved by drawing a random number r in the interval $[0; M^{-1}[$, where M is the number of samples to be drawn at time t. The algorithm in Table 4.4 then selects particles by repeatedly adding the fixed amount M^{-1} to r and by choosing the particle that corresponds to the resulting number. Any number u in [0;1] points to exactly one particle, namely the particle i for which

$$i = \underset{j}{\operatorname{argmin}} \sum_{m=1}^{j} w_t^{[m]} \ge u \tag{4.38}$$

The while loop in Table 4.4 serves two tasks, it computes the sum in the right-hand side of this equation and additionally checks whether i is the index of the first particle such that the corresponding sum of weights exceeds u. The selection is then carried out in Line 12. This process is also illustrated in Figure 4.3.

The advantage of the low-variance sampler is threefold. First, it covers the space of samples in a more systematic fashion than the independent random sampler. This should be obvious from the fact that the dependent sampler cycles through all particles systematically, rather than choosing them independently at random. Second, if all the samples have the same importance factors, the resulting sample set $\bar{\mathcal{X}}_t$ is equivalent to \mathcal{X}_t so that no samples are lost if we resample without having integrated an observation into \mathcal{X}_t . Third, the low-variance sampler has a complexity of O(M). Achieving the same complexity for independent sampling is difficult; obvious implementations require a $O(\log M)$ search for each particle once a random number has been drawn, which results in a complexity of $O(M \log M)$ for the entire resampling process. Computation time is of essence when using particle filters, and often an efficient implementation of the resampling process can make a huge difference in the practical performance. For these

reasons, most implementations of particle filters in robotics tend to rely on mechanisms like the one just discussed.

In general, the literature on efficient sampling is huge. Another popular option is *stratified sampling*, in which particles are grouped into subsets. The number of samples in each subset can be kept the same over time, regardless of the total weight of the particles contained in each subset. Such techniques tend to perform well when a robot tracks multiple, distinct hypotheses with a single particle filter.

3. A third source of error pertains to the divergence of the proposal and target distribution. We already hinted at the problem above, when discussing importance sampling. In essence, particles are generated from a proposal distribution that does not consider the measurement (cf., Equation (4.28)). The target distribution, which is the familiar Bayes filter posterior, depends of course on the measurement. The efficiency of the particle filter relies crucially on the 'match' between the proposal and the target distribution. If, at one extreme, the sensors of the robot are highly inaccurate but its motion is very accurate, the target distribution will be similar to the proposal distribution and the particle filter will be efficient. If, on the other hand, the sensors are highly accurate but the motion is not, these distributions can deviate substantially and the resulting particle filter can become arbitrarily inefficient. An extreme example of this would be a robot with deterministic sensors. For most deterministic sensors, the support of the measurement probability $p(z \mid x)$ will be limited to a submanifold of the state space. For example, consider a mobile robot that performs localization with noise-free range sensors. Clearly, $p(z \mid x)$ will be zero for almost every state x, with the exceptions of those that match the range measurement z exactly. Such a situation can be fatal: the proposal distribution will practically never generate a sample x which exactly corresponds to the range measurement z. Thus, all importance weights will be zero with probability one, and the resampling step becomes illconditioned. More generally, if $p(z \mid x)$ is degenerate, meaning that its support is restricted to a manifold of a smaller dimension than the dimension of the state space, the plain particle filter algorithm is inapplicable.

There exist a range of techniques for overcoming this problem. One simple-minded technique is to simply assume more noise in perception than there actually is. For example, one might use a measurement model $p(z \mid x)$ that overestimates the actual noise in the range measurements. In many implementations, such a step improves the accuracy of the particle filter—despite the oddity of using a knowingly incorrect measurement probability. Other techniques involve modifications of the proposal distribution in ways that incorporate the measurement. Such techniques will be discussed in later chapters of this book.

4. A fourth and final disadvantage of the particle filter is known as the *particle de- privation problem*. When performing estimation in a high-dimensional space,

there may be no particles in the vicinity to the correct state. This might be because the number of particles is too small to cover all relevant regions with high likelihood. However, one might argue that this ultimately must happen in any particle filter, regardless of the particle set size M. Particle deprivation occurs as the result of random resampling; an unlucky series of random numbers can wipe out all particles near the true state. At each resampling step, the probability for this to happen is larger than zero (although it is usually exponentially small in M). Thus, we only have to run the particle filter long enough. Eventually, we will generate an estimate that is arbitrarily incorrect.

In practice, problems of this nature only tend to arise when M is small relative to the space of all states with high likelihood. A popular solution to this problem is to add a small number of randomly generated particles into the set after each resampling process, regardless of the actual sequence of motion and measurement commands. Such a methodology can reduce (but not fix) the particle deprivation problem, but at the expense of an incorrect posterior estimate. The advantage of adding random samples lies in its simplicity: The software modification necessary to add random samples in a particle filter is minimal. As a rule of thumb, adding random samples should be considered a measure of last resort, which should only be applied if all other techniques for fixing a deprivation problem have failed.

This discussion showed that the quality of the sample based representation increases with the number of samples. An important question is therefore how many samples should be used for a specific estimation problem. Unfortunately, there is no perfect answer to this question and it is often left to the user to determine the required number of samples. As a rule of thumb, the number of samples strongly depends on the dimensionality of the state space and the uncertainty of the distributions approximated by the particle filter. For example, uniform distributions require many more samples than distributions focused on a small region of the state space. A more detailed discussion on sample sizes will be given in the context of robot localization, when we consider adaptive particle filters (see Section ??).

4.3 SUMMARY

This section introduced two nonparametric Bayes filters, histogram filters and particle filters. Nonparametric filters approximate the posterior by a finite number of values. Under mild assumptions on the system model and the shape of the posterior, both have the property that the approximation error converges uniformly to zero as the the number of values used to represent the posterior goes to infinity.

■ The histogram filter decomposes the state space into finitely many convex regions. It represents the cumulative posterior probability of each region by a single numerical value.

- There exist many decomposition techniques in robotics. In particular, the granularity of a decomposition may or may not depend on the structure of the environment. When it does, the resulting algorithms are often called "topological."
- Decomposition techniques can be divided into static and dynamic. Static decompositions are made in advance, irrespective of the shape of the belief. Dynamic decompositions rely on specifics of the robot's belief when decomposing the state space, often attempting to increase spatial resolution in proportion to the posterior probability. Dynamic decompositions tend to give better results, but they are also more difficult to implement.
- An alternative nonparametric technique is known as particle filter. Particle filters represent posteriors by a random sample of states, drawn from the posterior. Such samples are called particles. Particle filter are extremely easy to implement, and they are the most versatile of all Bayes filter algorithms represented in this book.
- Specific strategies exist to reduce the error in particle filters. Among the most popular ones are techniques for reducing the variance of the estimate that arises from the randomness of the algorithm, and techniques for adapting the number of particles in accordance with the complexity of the posterior.

The filter algorithms discussed in this and the previous chapter lay the groundwork for most probabilistic robotics algorithms discussed throughout the remainder of this book. The material presented here represents many of today's most popular algorithms and representations in probabilistic robotics.

4.4 BIBLIOGRAPHICAL REMARKS
